It was also possible during the past few years to considerably lower the particulate emissions which are typical for the diesel engine. The popularity of the high speed diesel engine in the passenger car though, would have been impossible without the diesel fuel injection systems from Bosch. The very high level of precision inherent in the distributor pump means that it is possible to precisely meter extremely small injection quantities to the engine. And thanks to the special governor installed with the VE pump in passenger car applications, the engine responds immediately to even the finest change in accelerator pedal setting. The cylinder charge heats up even further and the cylinder pressure increases again. For this reason, DI engines are used in all commercial vehicles and trucks. On the other hand, due to their lower noise level, prechamber engines are fitted in passenger cars where comfort plays a more important role than it does in the commercial vehicle sector. In addition, the prechamber diesel engine features considerably lower toxic emissions HC and NOX, and is less costly to produce than the DI engine. The fact though that the prechamber engine uses slightly more fuel than the DI engine 10.15% is leading to the DI engine coming more and more to the forefront. Compared to the gasoline engine, both diesel versions are more economical especially in the part load range.

Die\ Diesel engines are particularly suitable for use with exhaust gas turbochargers or mechanical superchargers. Using an exhaust gas turbocharger with the diesel engine increases not only the power yield, and with it the efficiency, but also reduces the combustion noise and the toxic

content of the exhaust gas. Diesel engine exhaust emissions A variety of different combustion deposits are formed when diesel fuel is burnt. These reaction products are dependent upon engine design, engine power output, and working load. The complete combustion of the fuel leads to major reductions in the formation of toxic substances. Complete combustion is supported by the careful matching of the air-fuel mixture, absolute precision in the injection process, and optimum air-fuel mixture turbulence. In the first place, water H<sub>2</sub>O and carbon dioxide CO<sub>2</sub> are generated. This is of particular importance in commercial applications. As the name implies, this comprises the pump barrel and the corresponding plunger. The pump camshaft is integrated in the pump and driven by the engine, forces the pump plunger in the delivery direction. The plunger is returned by its spring. The plunger and barrel assemblies are arranged inline, and plunger lift cannot be varied. By way of an actuator shaft, this can vary the plunger lift to port closing, and with it the start of delivery and the start of injection. Compared to the standard PE inline injection pump therefore, the control sleeve version features an additional degree of freedom. Distributor fuel injection pumps Distributor pumps have a mechanical flyweight governor, or an electronic control with integrated timing device. Pressure generation, and distribution to the individual engine cylinders, is the job of a central piston which runs on a cam plate. For one revolution of the driveshaft, the piston performs as many strokes as there are engine cylinders.

<http://eastbaysscanning.com/images/canon-sd600-operating-manual.pdf>

The rotating reciprocating movement is imparted to the plunger by the cams on the underside of the cam plate which ride on the rollers of the roller ring. On the conventional VE axial piston distributor pump with mechanical flyweight governor, or electronically controlled actuator, a control collar defines the effective stroke and with it the injected fuel quantity. On the conventional solenoid valve controlled axial piston distributor pump, instead of a control collar an electronically controlled high pressure solenoid valve controls the injected fuel quantity. A radial piston pump with cam ring and two to four radial pistons is responsible for Diesel fuel injection systems. An overview for generation of the high pressure and for fuel delivery. The injected fuel quantity is metered by a high pressure solenoid valve. They have no camshaft of their own, although they correspond to the PE inline injection pumps regarding their method of operation. In the case of large engines, the mechanical hydraulic governor or electronic controller is attached directly to the engine block. The fuel quantity adjustment as defined by the governor or controller is transferred by a rack integrated in the engine. The actuating cams for the individual PF single plunger pumps are located on the engine camshaft. This means that injection timing cannot be implemented by rotating the camshaft. It is a modular high pressure injection system. Similar to the UIS, the UPS system features one UPS single plunger injection pump for each engine cylinder. The use of a high speed electronically triggered solenoid valve enables the characteristic of the individual injection process, the so-called rate of discharge curve, to be precisely defined. Accumulator injection system Common Rail system CR Pressure generation and the actual injection process have been decoupled from each other in the Common Rail accumulator injection system.

<http://gtisupplies.com/images/canon-sd700-is-user-manual.pdf>

The injection pressure is generated independent of engine speed and injected fuel quantity, and is stored, ready for each injection process, in the rail fuel accumulator. A rotating reciprocating movement is imparted to the distributor plunger by way of the cam plate which is driven by the input shaft and rides on the rollers of the roller ring. The plunger moves inside the distributor head which is bolted to the pump housing. If the distributor pump is also equipped with a mechanical fuel shutoff device this is mounted in the governor cover. The governor assembly

comprising the flyweights and the control sleeve is driven by the drive shaft gear with a rubber damper via a gear pair. The governor linkage mechanism which consists of the control, starting, and tensioning levers, can pivot in the housing. The governor shifts the position of the control collar on the pump plunger. The governor cover forms the top of the distributor pump, and also contains the full load adjusting screw, the overflow restriction or the overflow valve, and the engine speed adjusting screw. For 4 stroke engines, the pump is driven at exactly half the engine crankshaft speed, in other words at camshaft speed. Distributor pumps are available for clockwise and for counterclockwise rotation, whereby the injection sequence differs depending upon the direction of rotation. The fuel outlets though are always supplied with fuel in their geometric sequence, and are identified with the letters A, B, C etc. It delivers a virtually constant flow of fuel per revolution to the interior of the injection pump. A pressure control valve is fitted to ensure that a defined injection pump interior pressure is maintained as a function of supply pump speed. Using this valve, it is possible to set a defined pressure for a given speed. Some of the fuel flows through the pressure regulating valve and returns to the suction side.

Some fuel also flows through the overflow restriction and back to the fuel tank in order to provide cooling and self venting for the injection pump Fig. 2. An overflow valve can be fitted instead of the overflow restriction.

**Fuelling configuration**

For the injection pump to function efficiently it is necessary that its high pressure stage is continually provided with pressurized fuel which is free of vapor bubbles. Normally, in the case of passenger cars and light commercial vehicles, the difference in height between the fuel tank and the fuel injection equipment is negligible. Furthermore, the fuel lines are not too long and they have adequate internal diameters. As a result, the engine supply pump in the injection pump is powerful enough to draw the fuel out of the fuel tank and to build up sufficient pressure in the interior of the injection pump. In those cases in which the difference in height between fuel tank and injection pump is excessive and or the fuel line between tank and pump is too long, a pre supply pump must be installed. This overcomes the resistances in the fuel line and the fuel filter.

**Gravity feed tanks** are mainly used on stationary engines.

**Fuel tank**

The fuel tank must be of noncorroding material, and must remain free of leaks at double the operating pressure and in any case at 0.3 bar. Suitable openings or safety valves must be provided, or similar measures taken, in order to permit excess pressure to escape of its own accord. Fuel must not leak past the filler cap or through pressure compensation devices. The fuel tank and the engine must be so far apart from each other that in case of an accident there is no danger of fire.

[audiomaster.se/wp-content/plugins/formcraft/file-upload/server/content/files/1626c6f480f0ab---canon-printer-ip3500-manual.pdf](http://audiomaster.se/wp-content/plugins/formcraft/file-upload/server/content/files/1626c6f480f0ab---canon-printer-ip3500-manual.pdf)

In addition, special regulations concerning the height of the fuel tank and its protective shielding apply to vehicles with open cabins, as well as to tractors and buses.

**Fuel lines**

As an alternative to steel pipes, flame inhibiting, steel braid armored flexible fuel lines can be used for the low pressure stage. This means that a fuel filter specifically aligned to the requirements of the fuel injection system is absolutely imperative if trouble free operation and a long service life are to be achieved. Fuel can contain water in bound form emulsion or unbound form e.g., condensation due to temperature changes. If this water gets into the injection pump, corrosion damage can be the result. Distributor pumps must therefore be equipped with a fuel filter incorporating a water accumulator from which the water must be drained off at regular intervals. At the same time, some of the fuel flows through a second passage to the pressure control valve.

**Pressure control valve**

The pressure control valve Fig. 5 is connected through a passage to the upper outlet kidney shaped recess, and is mounted in the immediate vicinity of the fuel supply pump. It permits a variable amount of fuel to return to the fuel tank through a narrow passage. The pressurized fuel then travels to the injection nozzles

through the delivery valves and the fuel injection tubing. Distributor plunger drive The rotary movement of the drive shaft is transferred to the distributor plunger via a coupling unit Fig. 7, whereby the dogs on cam plate and drive shaft engage with the recesses in the yoke, which is located between the end of the drive shaft and the cam plate. The distributor plunger is forced upwards to its TDC position by the cams on the cam plate, and the two symmetrically arranged plunger return springs force it back down again to its BDC position.

The plunger return springs abut at one end against the distributor head and at the other their force is directed to the plunger through a link element. These springs also prevent the cam plate jumping off the rollers during harsh acceleration. The lengths of the return springs are carefully matched to each other so that the plunger is not displaced from its centered position Fig. 8. Cam plates and cam contours The cam plate and its cam contour influence the fuel injection pressure and the injection duration, whereby cam stroke and plunger lift velocity are the decisive criteria. Considering the different combustion chamber configurations and combustion systems used in the various engine types, it becomes imperative that the fuel injection factors are individually tailored to each other. For this reason, a special cam plate surface is generated for each engine type and machined into the cam plate face. This defined cam plate is then assembled in the corresponding distributor pump. Small leakage losses are nevertheless unavoidable, as well as being desirable for plunger lubrication. For this reason, the distributor head is only to be replaced as a complete assembly, and never the plunger, control collar, or distributor flange alone. Fuel metering The fuel delivery from a fuel injection pump is a dynamic process comprising several stroke phases Fig. 9. The pressure required for the actual fuel injection is generated by the high pressure pump. It has the job of relieving the pressure in the line by removing a defined volume of fuel upon completion of the delivery phase. This ensures precise closing of the injection nozzle at the end of the injection process. At the same time, stable pressure conditions between injection pulses are created in the high pressure lines, regardless of the quantity of fuel being injected at a particular time. The delivery valve is a plunger type valve.

During delivery, the pressure generated in the high pressure chamber above the plunger causes the delivery valve to open. This though generates pressure waves which are reflected at the delivery valve. These cause the delivery valve to open again, or cause vacuum phases in the high pressure line. These processes result in postinjection of fuel with attendant increases in exhaust emissions or cavitation and wear in the injection line or at the nozzle. To prevent such harmful reflections, the delivery valve is provided with a restriction bore which is only effective in the direction of return flow. The high pressure lines connect the injection pump to the injection nozzles and are routed so that they have no sharp bends. Apart from this, upon driving off the engine must not tend to stall. The engine must respond to accelerator pedal changes by accelerating or decelerating smoothly and without hesitation. On the flat, or on a constant gradient, with the accelerator pedal held in a given position, the vehicle speed should also remain constant. When the pedal is released the engine must brake the vehicle. It is a sensitive control device which determines the position of the control collar, thereby defining the delivery stroke and with it the injected fuel quantity. Depending upon type, the governor is also responsible for keeping certain engine speeds constant, such as idle speed, or the minimum and maximum engine speeds of a stipulated engine speed range, or of the complete speed range, between idle and maximum speed. Within certain limits, these governors can also maintain the engine speeds between idle and maximum constant. Within the speed control range, the increase in engine speed is not to exceed a given figure. This is stipulated as the high idle speed. This is the engine speed which results when the diesel engine, starting at its maximum speed under full load, is relieved of all load.

For instance, on an engine used to power an electrical generator set, a small speed droop is required so that load changes result in only minor speed changes and therefore minimal frequency changes. On the other hand, for automotive applications large speed droops are preferable because these result in more stable control in case of only slight load changes acceleration or deceleration and lead to better driveability. The variable speed governor is also often fitted in commercial and agricultural vehicles tractors and combine harvesters.

**Design and construction**  
 The governor assembly is driven by the drive shaft and comprises the flyweight housing complete with flyweights. The governor assembly is attached to the governor shaft which is fixed in the governor housing, and is free to rotate around it. When the flyweights rotate they pivot outwards due to centrifugal force and their radial movement is converted to an axial movement of the sliding sleeve. The sliding sleeve travel and the force developed by the sleeve influence the governor lever assembly. This comprises the starting lever, tensioning lever, and adjusting lever not shown. The interaction of spring forces and sliding sleeve force defines the setting of the governor lever assembly, variations of which are transferred to the control collar and result in adjustments to the injected fuel quantity.

**Starting**  
 With the engine at standstill, the flyweights and the sliding sleeve are in their initial position Fig. 3a. The starting lever has been pushed to the start position by the starting spring and has pivoted around its fulcrum M2. At the same time the control collar on the distributor plunger has been shifted to its Axial piston distributor pumps 24

**Variable speed governor.** It can be shifted by the fuel delivery adjusting screw not shown in Figure 3.

Similarly, the start lever and tensioning lever are also able to rotate in the adjusting lever. A ball pin which engages in the control collar is attached to the underside of the start lever, and the start spring to its upper section. The idle spring is attached to a retaining pin at the top end of the tensioning lever. Also attached to this pin is the governor spring. The connection to the engine speed control lever is through a lever and the control lever shaft. It only needs a very low speed for the sliding sleeve to shift against the soft start spring by the amount  $a$ . In the process, the start lever pivots around fulcrum M2 and the start quantity is automatically reduced to the idle quantity.

**Low speed control**  
 With the engine running, and the accelerator pedal released, the engine speed control lever shifts to the idle position Figure 3b up against the idle speed adjusting screw. The idle speed is selected so that the engine still runs reliably and smoothly when unloaded or only slightly loaded. At speeds above idle, the spring has been compressed by the amount  $c$  and is no longer effective. Using the special idle spring attached to the governor housing, this means that idle speed can be adjusted independent of the accelerator pedal setting, and can be increased or decreased as a function of temperature or load.

**Operation under load**  
 During actual operation, depending upon the required engine speed or vehicle speed, the engine speed control lever is in a given position within its pivot range. This is stipulated by the driver through a given setting of the accelerator pedal. At engine speeds above idle, start spring and idle spring have been compressed completely and have no further effect on governor action.

As a result of this adjustment of the control lever position, the governor spring is tensioned by a given amount, with the result that the governor spring force exceeds the centrifugal force of the flyweights and causes the start lever and the tensioning lever to pivot around fulcrum M2. As a result, the delivery quantity is increased and the engine speed rises. This means that during operation, and as long as the engine is not overloaded, every position of the engine speed control lever is allocated to a specific speed range between full load and zero. The result is that within the limits set by its speed droop, the governor maintains the desired speed Fig. 4. If the load increases to such an extent for instance on a gradient that even though the control collar is in the full load position the engine speed continues to drop, this indicates that it is impossible to increase fuel delivery any further. This causes the flyweights to move outwards so that the

sliding sleeve presses against the tensioning and start levers. Both levers change their position and push the control collar in the direction of less fuel delivery until a reduced fuel delivery figure is reached which corresponds to the new loading level. At the extreme, the delivery figure is zero. The speed range between these points is directly controlled by the accelerator pedal Fig. 6.

**Design and construction**

The governor assembly with flyweights, and the lever configuration, are comparable with those of the variable speed governor already dealt with. The main difference lies in the governor spring and its installation. It is in the form of a compression spring and is held in a guide element. Tensioning lever and governor spring are connected by a retaining pin.

**Starting**

With the engine at standstill, the flyweights are also stationary and the sliding sleeve is in its initial position.

This enables the starting spring to push the flyweights to their inner position through the starting lever and the sliding sleeve. On the distributor plunger, the control collar is in the start quantity position.

**Idle control**

Once the engine is running and the accelerator pedal has been released, the engine speed control lever is pulled back into the idle position by its return spring. The centrifugal force generated by the flyweights increases along with engine speed Fig. 7a and the inner flyweight legs push the sliding sleeve up against the start lever. The idle spring on the tensioning lever is responsible for the controlling action. The starting and idle springs are no longer effective and the intermediate spring comes into effect. If the engine speed control lever is pressed even further in the fullload direction, the intermediate spring is compressed until the tensioning lever abuts against the retaining pin Fig. 7b. The intermediate spring is now ineffective and the uncontrolled range has been entered. This uncontrolled range is a function of the governor spring pretension, and in this range the spring can be regarded as a solid element. The accelerator pedal position engine speed control lever is now transferred directly through the governor lever mechanism to the control collar, which means that the injected fuel quantity is directly determined by the accelerator pedal. Example Fig. 1

Start of delivery FB takes place after the inlet port is closed. The high pressure then builds up in the pump which, as soon as the nozzle opening pressure has been reached leads to the start of injection SB. The period between FB and SB is referred to as the injection lag SV. The increasing compression of the airfuel mixture in the combustion chamber then initiates the ignition VB. The period between SB and VB is the ignition lag ZV.
